(Received 6 December 2006; published 16 April 2007)

The temperature dependence of the Hall conductivity is reported at mid- and far-IR frequencies for cleaved single crystals. A nearly simple Drude behavior is observed with a scattering rate that is linear in temperature and nearly frequency independent. The Hall data are in good agreement with calculations based on the fluctuation-exchange interaction when current vertex corrections are included. The $\sigma_{\text{xx}}$ quasiparticle spectral weight is suppressed to 0.09 times the band value, compared with 0.33 times the band value for $\sigma_{\text{xy}}$.

DOI: 10.1103/PhysRevB.75.140506

While significant progress has been made toward an understanding of the cuprate superconductors due in large part to important new experimental data from angle-resolved photoemission spectroscopy (ARPES), neutron scattering, and IR measurements, a clear microscopic theory remains elusive. Indeed, a theory of the superconductivity and transport properties of these strongly correlated materials continues as a central problem in modern condensed matter physics. The correlations with magnetic fluctuations have been elucidated by neutron scattering,\textsuperscript{1} and the nature and occurrence of quasiparticles near the Fermi surface and in different phases have been mapped by ARPES.\textsuperscript{2} Evidence is accumulating that the underdoped cuprates, particularly electron-doped materials, support spin density waves which partially gap the Fermi surface.\textsuperscript{3,4} The optimally doped cuprates, however, are found to have a large nearly circular Fermi surface with quasiparticles that are well defined in the $(\pi, \pi)$ direction and somewhat less well defined in the $(\pi, 0)$ direction. The linear temperature-dependent resistivity is found to correspond to the linearly temperature-dependent quasiparticle imaginary self-energy. At optimal doping the cuprates do not exhibit significant evidence for the pseudogap observed in underdoped materials.\textsuperscript{5} Nevertheless, anomalous transport properties of the nearly optimally doped cuprates are universally observed. One such anomaly is the temperature dependence of the Hall coefficient which has frequently been cited as evidence of the non-Fermi-liquid character of the cuprates.

One important approach to understanding the magnetotransport anomalies as well as other transport anomalies of the cuprates is to include vertex corrections in the conductivity within Fermi liquid theory. Kontani and Yamada\textsuperscript{6} have examined this approach using the spin fluctuation exchange interaction between carriers and include current vertex corrections in the conductivity. They find that the current vertex corrections enter into $\sigma_{\text{xx}}$ more significantly than in $\sigma_{\text{xy}}$ and that this theory is capable of explaining the anomalous dc magnetotransport of the optimally doped cuprates in terms of the temperature dependence of the spin-fluctuation-induced interaction. More recently, Kontani\textsuperscript{7} has examined the IR frequency dependence of magnetotransport with further success, which further highlights the possibility that strong correlations may enter the diagonal and off-diagonal conductivities differently. This insight suggests that $\sigma_{\text{xy}}$ may be a more useful quantity to study than the Hall angle $\theta_H$ as representative of optimally doped BSCCO. In this work we examine the temperature dependence of $\sigma_{\text{xy}}$ in optimally doped Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ [BSCCO(2212)] which does not have conduction by chains that complicated the interpretation of the IR Hall data for YBa$_2$Cu$_3$O$_7$ of earlier work.\textsuperscript{5} We find that, for frequencies around 10 meV and 100 meV, $\sigma_{\text{xy}}$ is consistent with a nearly simple Drude form in contrast to both $\sigma_{\text{xx}}$ and $\theta_H$. The parameters of the Drude form are evaluated and compared with other transport properties, with theoretical calculations based on Kontani\textsuperscript{7} and with the $\sigma_{\text{xx}}$ sum rule.

The experimental system of the current work measures the very small complex Faraday angle imparted to CO$_2$ laser radiation traveling perpendicular to and transmitted by the sample, which is immersed in a magnetic field also perpendicular to its surface. The system is the same as that used by in the earlier YBCO study\textsuperscript{8} with the addition of an in-line calibration system and a continuous stress-free temperature scan provision.\textsuperscript{9} The sample of the current work was cleaved, or rather peeled, from a bulk single crystal of Bi$_2$Sr$_2$CaCu$_2$O$_{8+\delta}$ grown by the traveling floating zone method.\textsuperscript{10} The resulting 100-nm-thick film was placed in thermal contact with a supporting wedged BaF$_2$ substrate. Measurement of the ac magnetic susceptibility of this mounted, peeled segment revealed a $T_c$ of 92 K with a width of less than 1 K. This measurement was performed after all of the Hall measurements had been completed, thus establishing the integrity of the sample and recommending the Hall data as representative of optimally doped BSCCO. The far-infrared measurements were performed on a similarly peeled sample of BSCCO mounted onto a quartz substrate. The measurement apparatus used a molecular vapor laser as the source and a detection system similar to that of Grayson et al.\textsuperscript{11} Infrared conductivity data,\textsuperscript{12} from measurements performed on bulk crystals from the same batch, supplied the real and imaginary parts of the longitudinal conductivity
\[ \sigma_{xx} = \frac{S_{xx}}{\gamma_{xx} - i\omega[1 + \lambda(T,\omega)]} = \frac{S_{xx}^*}{\gamma_{xx} - i\omega}, \]  
\[ \sigma_{xy} = \frac{S_{xy}}{(\gamma_{xy} - i\omega[1 + \lambda(T,\omega)])^2} = \frac{S_{xy}^*}{(\gamma_{xy} - i\omega)^2}, \]  
where \( S_{xx} \) and \( S_{xy} \) are the longitudinal and transverse spectral weights defined here as

\[ S_{xx} = \int_0^{\Omega_c} \frac{2}{\pi} \operatorname{Re} \sigma_{xx} d\omega, \]
\[ S_{xy} = \int_0^{\Omega_c} \frac{2}{\pi} \operatorname{Im} \sigma_{xy} d\omega, \]

where \( \Omega_c \) as a cutoff frequency high enough that the imaginary part of the quasiparticle self-energy is saturated but still below the Mott-Hubbard gap. The measured quantities in the IR Hall experiment at fixed frequency actually relate to \( S_{xy}^* \) = \( \omega/\operatorname{Im}(\sigma_{xy}^{1/2}) \) = \( S_{xy}(1 + \lambda_{xy})^{-2} \). This form recognizes the fact that the longitudinal and transverse scattering rates \( \gamma_{xx} \) and \( \gamma_{xy} \) may be different. In fact, attempts to analyze the data under the assumption that they are identical leads to nonphysical results. Consider that with \( \gamma_{xx}^* = \gamma_{yy}^* = \gamma^* \), then from \( \theta_H = \sigma_{xx}/\sigma_{xx} \)

\[ \theta_H = \gamma^* \frac{\omega}{\omega_H} - \omega \frac{\omega}{\omega_H}, \]

where \( \omega_H = S_{xx}^* / S_{xx}^* \). From Fig. 1 we see that Eq. (5) implies a normal-state scattering rate with a negative projection below 50 K and a Hall mass of 2.9m_0, which, though similar in magnitude to the ARPES-measured mass, increases with temperature. Such unconventional results challenge this simple analysis and suggest that the effective longitudinal

and transverse scattering rates are different. Therefore in this paper we examine the transverse conductivity \( \sigma_{xy} \) independently.

Figure 2 displays the data in terms of \( \sigma_{xy} \). The renormalized transverse scattering rate from Eq. (2) is simply

\[ \gamma_{xy}^2 = -\omega \frac{\operatorname{Re}(\sigma_{xy}^{1/2})}{\operatorname{Im}(\sigma_{xy}^{1/2})}, \]  

This alternative analysis of the data results in a transverse scattering rate \( \gamma_{xy}^* \) which is everywhere positive, increases linearly with temperature and has a zero temperature projection of 200 cm\(^{-1}\). This analysis also results in a transverse spectral weight which increases slightly with temperature. Remarkably, this observed temperature behavior of the transverse conductivity as well captured by the calculated results of the fluctuation exchange approximation with current vertex corrections (FLEX+CVC) for La_{2-x}Sr_{x}CuO_{4} at 10% doping shown as solid circles in Fig. 2. Similar results are obtained for \( \text{YBa}_2\text{Cu}_3\text{O}_7 \) calculations. In the relaxation time approximation, where the CVC is dropped, \( \operatorname{Re}(\sigma_{xy}^{1/2}) \) drops to zero as \( \gamma^* \) (\( \omega \)) and is approximately temperature independent for \( \hbar \omega \gg k_B T \). According to the calculations, the approximate linear temperature behavior of \( \operatorname{Re}(\sigma_{xy}^{1/2}) \) is caused by the CVC due to spin fluctuations, which are strongly temperature dependent. The existence of the CVC is a consequence of conservation laws, which intimately govern the transport phenomena. Consequently, neglecting the CVC frequently leads to nonphysical predictions. In these calculated results the vertex corrections enter into \( \sigma_{xx} \) quite differently from \( \sigma_{xy} \). Although the CVC is less effective as the doping increases, a similar numerical result is obtained even at 15% doping if we use a larger value of the Coulomb interaction \( U \), which is the single adjustable parameter of the theory.

Additionally, the FLEX+CVC approximation captures the frequency behavior of the transverse conductivity as well. To examine this frequency dependence we introduce the data shown in Fig. 3 for optimally doped BSCCO at 84 cm\(^{-1}\). Measurements were also performed at 24 and 42 cm\(^{-1}\) and proved to be consistent with those shown. These far-infrared data, multiplied by \( \sigma_{xx} \), to produce \( \sigma_{xy} \),
appear in Fig. 4 along with the midinfrared data and two frequency points from the FLEX+CVC calculations.

Since \( \text{Im}(\sigma_{xy}^{-1/2})/\omega \) is found to be nearly independent of temperature and frequency over the measured infrared range, it is interesting to consider the observed values in more general terms. The extended Drude model in Eq. (2) relates \( \text{Im}(\sigma_{xy}^{-1/2}) \) to the Drude spectral weight. Generally, for strongly interacting systems near a Mott transition, one expects \( \lambda_{xy} \to 0 \) and \( \gamma_{xy} \) to saturate at frequencies \( \omega_s < \Omega_c \) as the measurement frequency exceeds the saturation frequency (typically \( \sim 400 \) meV for cuprates) while still remaining below the Mott-Hubbard gap. This is the observed behavior of \( \sigma_{xx}(\omega) \) in the optimally hole doped cuprates.\(^{15} \)

Assuming the same interaction energy scale for the transverse conductivity, the data allow us to characterize the Drude peak in \( \sigma_{xy} \), which is at a frequency \( \omega \approx \gamma_{xy}^s \). We can compare \( S_{xy}^s \) and \( \gamma_{xy}^s \) at far-IR and mid-IR frequencies obtained from Eq. (2). The results are shown in Table I, which summarizes experimental results in terms of the scattering rates and spectral weights along with the longitudinal scattering rates from \( \sigma_{xx} \). In the table, \( \gamma_{xy}^s(84) \) is comparable to \( \gamma_{xx}^s \); however, \( \gamma_{xy}^*(950) \) is much less than \( \gamma_{xx}^*(950) \), corresponding to a weaker frequency-dependent scattering. Therefore, we expect \( \lambda_{xy} < \lambda_{xx} \) and since \( \lambda_{xx} < 1 \) at 950 cm\(^{-1} \), we expect \( \lambda_{xy} \ll 1 \). This suggests that \( S_{xy} = S_{xx}^s(1 + \lambda_{xy})^{-2} \approx S_{xy}^s \) so that \( S_{xy}^s \) in the mid-IR frequencies should give a good approximate measure of the Drude contribution to the \( \sigma_{xy} \) sum rule. Further support for this is obtained by comparing \( S_{xy}^s \) in the mid- and far-IR frequencies from the table. It is seen that they are in good agreement, again consistent with a very weak frequency dependence of the optical self-energy \( S_{xy}(\omega) = \omega \lambda_{xy} + i \gamma_{xy} \) and \( \lambda_{xy} \ll 1 \). In fact these results indicate that \( S_{xy} \) has very nearly a simple Drude form in optimally doped BSCCO.

Since this analysis of the far-IR and mid-IR data appears to provide a measure of the partial sum \( S_{xy}^s \), it is interesting to compare the value to the band value which can be calculated from the general relation\(^{13} \)

\[
S_{xy}^{\text{band}} = e^2B \sum_k \text{det}(m_k^{-1})n_k, \tag{7}
\]

where

\[
m_k^{-1} = \frac{2^3 E(k)}{\hbar^2 \Omega k}, \tag{8}
\]

is the inverse mass tensor and \( n_k \) is the Fermi function. To calculate \( S_{xy}^{\text{band}} \) we use the tight-binding fit to the cuprate band structure:\(^{3} \)

\[
E(k_x, k_y) = -2t_1[(\cos(k_x) + \cos(k_y))] + 4t_2 \cos(k_x)\cos(k_y) - 2t_3[\cos(2k_x) + \cos(2k_y)], \tag{9}
\]

where \( t_1 = 0.38 \) eV, \( t_2 = 0.32t_1 \), and \( t_3 = 0.5t_2 \). At optimal doping, the electron density \( n \) is 0.84 and \( S_{xy}^{\text{band}} = 3.73 \times 10^{31} \) Hz/cm\(^2 \) and so \( S_{xy}^s/S_{xy}^{\text{band}} = 0.09 \). It is interesting to compare this observed reduction from \( S_{xy}^{\text{band}} \) with the behavior of \( S_{xx} = \omega_p^2/4 \pi \), where \( \omega_p \) is the bare plasma frequency. Using the band model we find \( S_{xy}^{\text{band}} = \frac{e^2}{2}\pi \text{det}(m_k^{-1}) \) \( \approx 3.50 \times 10^{30} \) Hz/cm\(^2 \) from the literature\(^{12,16} \) \( \omega_p = 16 \) 200 cm\(^{-1} \) so that \( S_{xy}^s/S_{xy}^{\text{band}} = 0.33 \). This compares with similar estimations for single layer \( Pr_{2-x}Ce_xCuO_4 \) and \( La_{2-x}Sr_xCO_3 \).\(^{3} \) Therefore we see that \( S_{xy} \) is more significantly suppressed than \( S_{xx} \). Indeed, \( S_{xy}^s/S_{xy}^{\text{band}} \approx (S_{xx}^s/S_{xx}^{\text{band}})^2 \). If interpreted as an effective mass, then \( S_{xy}/S_{xx} = \omega_p n_k \) and \( m_{pl}/m_0 = 6.7 \). The reduction in \( S_{xx} \) is associated with the Coulomb correlations due to the proximity to the Mott transition as has been discussed recently.\(^{3} \) There are no theoretical results for \( S_{xy} \). However, whether the reduction is to be thought of as a mass effect or a charge effect in Fermi liquid theory, a larger reduction of \( S_{xy} \) may be expected as \( S_{xx} \sim e^2/\pi m \) and \( S_{xy} \sim e^3/m^2 \). Therefore, theoretical predictions may be interesting and may give further insights into the strong correlations in the cuprates.

\[\]
In summary, measurements of $\sigma_{xx}$ in the infrared exhibit a nearly Drude behavior with a scattering rate linear in temperature, and only weakly frequency dependent, and a nearly temperature- and frequency-independent transverse spectral weight, which is only 0.09 of the band value. These results are in good agreement with calculations based on the fluctuation exchange model when current vertex corrections are included. Extending these IR Hall conductivity measurements over a wider frequency range in cuprates and other strongly correlated electron systems may provide significant new insights into the physics of these materials in the vicinity of a Mott transition.

We wish to thank A.J. Millis, S. Das Sarma, and V.M. Yakovenko for their stimulating discussions. We also wish to thank D.B. Romero, who peeled and mounted the BSCCO sample. This work was supported by the NSF under Grant No. DMR-0030112 and by the DOE under Contract No. DE-AC02-98CH10886.
